(Dated: December 22, 2021)

We consider a system of granular particles, modeled by two dimensional frictional elastic disks, that is exposed to externally applied time-dependent shear stress in a planar Couette geometry. We concentrate on the external forcing that produces intermittent dynamics of stick-slip type. In this regime, the top wall remains at rest until the applied stress becomes sufficiently large, and then it slips. We focus on the evolution of the system as it approaches a slip event. Our goal is to identify measures that show a potential for predicting that the system is about to yield. Our main finding is that static global measures, defined as system-wide averages, do not seem to be sensitive to an approaching slip event. On average, they tend to increase linearly with the force pulling the spring. On the other hand, the behavior of the time-dependent measures that quantify the evolution of the system on a micro (particle) or mesoscale changes dramatically before a slip event starts. These measures grow rapidly in magnitude as a slip event approaches, indicating a significant increase in fluctuations of the system before a slip event is triggered.

I. INTRODUCTION

Avalanches are phenomena that are well known on geological scales, with many familiar examples from earthquakes to snow avalanches and landslides. The distribution of the times between the avalanches and their sizes is statistically similar to the distribution of abrupt events observed in many other systems where the consequences are less spectacular but crucial to understanding material responses that are of significant technological importance. Relevant systems include dry and wet granular systems, suspensions, colloids, foams, yield-stress fluids, glass-forming materials, and several other soft matter systems relevant to our everyday life. The response of these systems to external driving is the subject of active research, with a large body of research considering an intermittent response where a system evolves via the stick-slip type of dynamics, see [1] for a review. Until recently, research concerning the predictability of upcoming events (slip, or avalanche) has been of a statistical nature. [2, 3]. In recent years, new approaches based on experimental information [4–7], in some cases coupled with machine learning approaches [8–10], have been considered. Despite progress, our ability to predict upcoming slips is still limited. Thus, it is important to devise more precise predictions, or at least to find out what type of information about the considered system is needed to make such predictions feasible.

The intermittent type of dynamics of granular systems is often explored because it provides a good testing ground for various theoretical approaches. In particular, both experiments and simulations provide detailed information about particles as well as their interactions. Experimentally, the interactions between the particles have been extensively analyzed by using methods based on photoelasticity [5, 11–16]. The same information can be obtained for a wide variety of systems [17–22] by rela-

tively straightforward simulations based on discrete element methods. Therefore, a significant amount of research has been carried out and here we mention only a few examples. Various statistical measures of intermittent dynamics have been considered in detail in simulations [18–21, 23], and experiments with particular focus on quantifying intermittency were reported as well [24]. The connections between different systems experiencing intermittency have been discussed extensively [25, 26] and significant progress has been reached in understanding how a system yields, in particular based on the shear transformation zone concept [2, 27, 28]. In Ref. [29], models for predicting an upcoming avalanche were introduced. The authors, among others, have discussed in detail the statistics of slip events. They showed that the statistics obtained for granular systems and the other soft matter systems listed above are similar.

One important question when considering intermittent dynamics is the relation between micro (particle scale) and macro (system size) behavior. The interactions between the particles can be captured by a force network. Visual inspection of these networks shows that local interactions between the particles give rise to organized structures that form spontaneously on a mesoscale (with a typical length scale of ten or so particle diameters). By now, it is widely accepted that the force networks play an important role in determining the system-wide response. However, it is still not clear how to extract relevant information about the intermittent dynamics from the properties of these networks, or some other particle-scale/mesoscale properties of the system.

Our main goal is to identify measures that exhibit a clear change in their trend as a system approaches a slip event, since finding such measures is the first and necessary step towards developing the ability to forecast slip events. To achieve this goal, we consider a simple system in two dimensional planar Couette geometry, with the

top boundary pulled by a harmonic spring, see Fig. 1. We investigate a wide variety of measures that quantify various properties of inter-particle contacts, forces (force networks), and particles' dynamics. Some of the measures are classical while others, based on persistent homology (PH), have been implemented recently [30–35]. We will show that global measures, obtained by averaging any of the considered quantities over the whole system, do not change their behavior as the system approaches a slip event. On the contrary, the measures quantifying the micro and mesoscopic evolution of the system on a short time scale start increasing nonlinearly well before the onset of the slip. Thus, these measures show significant potential for predicting an upcoming slip event. Our interpretation of this finding is that local time-dependent measures capture increasing fluctuations on micro and mesoscopic scales that lead to a slip event.

The rest of this manuscript is structured as follows. Section II focuses on the description of simulation techniques. In Sec. III we define the measures that we consider in this paper. Section IV provides the main results, motivated by consideration of a single slip event that is discussed in Sec. IV A. In Sec. IV B we start by providing an overview of the statistical analysis that we carry out, applied to the global measures in Sec. IV B 1, and then to the local ones in Sec. IV B 2. Section V is devoted to the summary and discussion of future directions. Animations of DEM simulations as well as of some of the considered measures are presented in Supplementary Materials.

II. SIMULATIONS

In this section, we provide a short overview of the considered simulations. We also explain how we store the relevant information about the system for the subsequent analysis. Since the simulation techniques are identical to the methods described in Ref. [36] we limit ourselves to a summary and refer the reader to earlier work [37] for the description of experiments carried out with photoelastic particles that provided the needed material parameters. In our simulations, we model granular particles as 2D soft frictional disks, and place $N = 2500$ disks (system particles) between two horizontal rough walls (made up of wall particles) placed parallel to the horizontal x axis, see Fig. 1. The system particles are bi-disperse, with 25% of large particles and 75% of small particles, and the diameter of a large particle is 25% larger than that of a small particle. The top wall is made of small particles spaced slightly apart from each other. This reduces the slip of the system particles along the wall. The bottom wall is also made of small particles but they are placed at a distance equal to the particle diameter. The bottom wall is kept fixed, while the top one is pulled by a harmonic spring moving with the velocity v_s in the $+x$ direction.

We use the linear spring-dashpot model to describe the interactions between the system particles and between

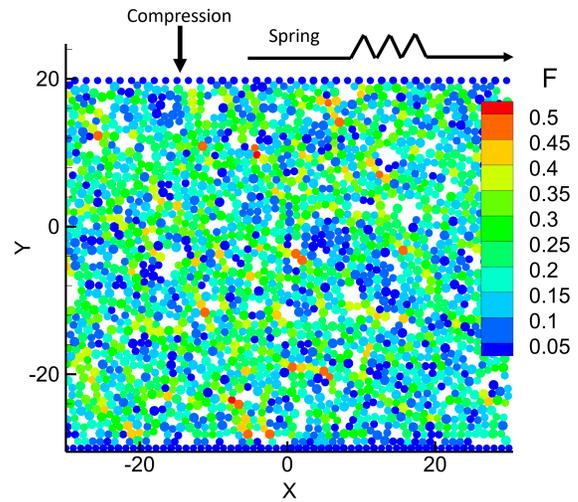

FIG. 1. Snapshot of the considered system. The system particles are colored by their total current force magnitude while the wall particles are shown in blue. The top wall is exposed to a linear force, in the $+x$ direction, by a spring and (constant) pressure force is applied in the $-y$ direction. The bottom wall is fixed.

system and wall particles. In what follows, we use the diameter of small particles, d , as the length scale, their mass, m , as the mass scale, and the binary collision time, τ_c , as the time scale. Motivated by experiments with photoelastic particles [37], we use $d = 1.27$ cm, $m = 1.32$ g, and $\tau_c = 1.25 \times 10^{-3}$ s, as appropriate for particles of Young modulus of $Y \approx 0.7$ MPa. For such value of τ_c , the normal spring constant is $k_n = m\pi^2/2\tau_c^2 \approx 4.93$ N/m, and the tangential spring constant (needed for modeling of tangential forces using the Cundall-Strack model [38]) is $k_t = 6k_n/7$, which is close to the value used previously [39]. The coefficient of static friction, μ , is equal to 0.7 for particle-particle contacts and $\mu = 2$ for particle-wall contacts; we choose the larger value for the latter to reduce slipping of particles adjacent to the walls. The force constant of the spring applied to the top wall, k_s , is significantly smaller than the one describing particle interactions, $k_s = k_n/400$. In addition, a normal compression force is applied in the $-y$ direction to model an externally applied pressure (force/length in 2D) of $p = 0.02$; gravitational effects are not included. It is well known that a sufficiently large p and sufficiently small spring speed, v_s , are needed for the system to enter stick-slip regime [18]; we find by experimenting that for $p = 0.02$ the value $v_s = 1.5 \times 10^{-3}$ is appropriate to induce stick-slip dynamics. We integrate Newton's equations of motion for both the translational and rotational degrees of freedom using a fourth-order predictor-corrector method with time step $dt = 0.02$. The states of the system, used to compute the quantities presented in this paper, are stored at times $\delta t = 10 \tau_c$ apart.

The simulation protocol starts by applying a pressure p to the top wall and then letting the system relax until

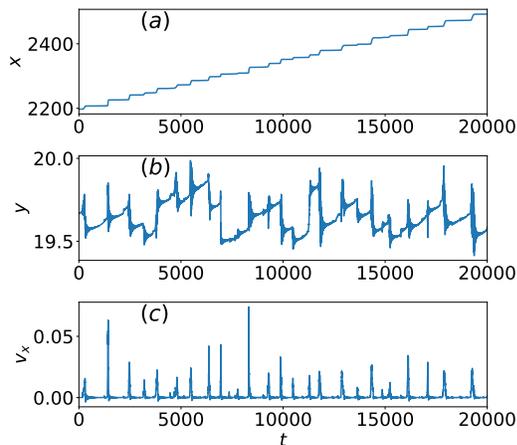

FIG. 2. Representative system evolution, shown on 20,000 consecutively sampled states, at the later part of the simulation. The time (horizontal) axis is given in units of the time step δt . (a) x position of the top wall, (b) y position of the top wall, and (c) top wall velocity, v_x , in the shearing direction.

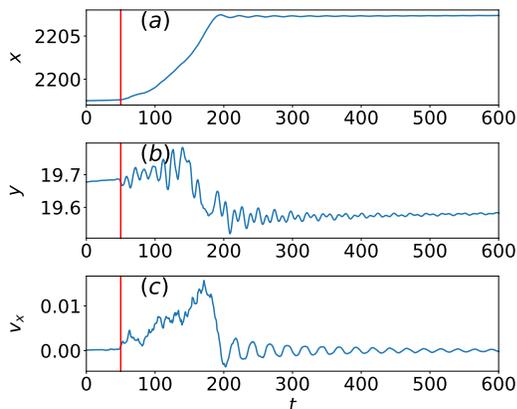

FIG. 3. Wall behavior around the first slip event depicted in Fig. 2. The red line indicates the time t_0 , defined in Sec. III A, at which the slips starts.

the ratio of kinetic/potential energy drops below 10^{-5} . Then, we start moving the spring. The wall remains at rest until the spring force becomes sufficiently large, and then it slips. Figure 2(a-c) shows a short time window of the wall positions in the x and y direction as well as the speed of the wall in the shearing direction, x . Figure 3 depicts the detailed behaviour during the first slip event, shown in Fig. 2, to illustrate typical dynamics. We note in passing that each slip is accompanied by a jump of the wall in the y direction, see Fig. 2(b) and Fig. 3(b). To reach reasonable statistics, we carry out simulations for a long time so that a large number (400-500) of slip events occur. The total number of data points (extracted every δt) is 3×10^5 .

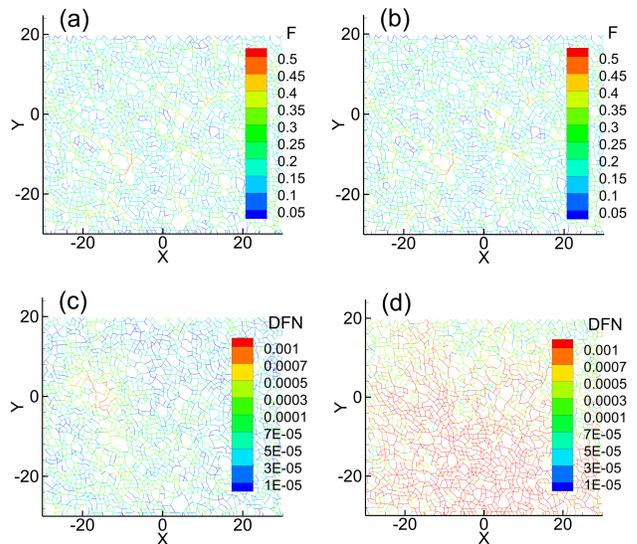

FIG. 4. Force and differential force networks for the slip event, shown in Fig. 3. (a) Force network before the onset of a slip event at time $t = t_0 - 20$ where t_0 is the time at which the slip event starts. (b) force network at the onset of a slip event at $t = t_0$, (c) differential force network at $t = t_0 - 20$ and (d) differential force network at $t = t_0$. Note that on the scale of a typical force in the force network shown in (a-b), the changes of the network (shown in (c-d)) are very small; for this reason the networks in (a-b) appear almost identical.

III. DEFINITIONS OF RELEVANT QUANTITIES

In this section, we present the measures that we use to analyze the behavior of the system before the onset of a slip event. We start by defining what we mean by the start and end of a slip event in Sec. III A. In Sec. III B we formalize the notion of the force networks and differential force networks that we use to study the evolution of the system. To quantify the structure of these networks and their evolution we use persistent homology (PH), which is a valuable tool of topological data analysis, see [40, 41] for a review, and [34, 42] for examples of applications. We will briefly explain the important concepts behind PH in Sec. III C. Finally, in Sec. III D we summarize the quantities that we use to characterize contacts between the particles.

A. Slip detection

To study the behavior of the system before the onset of a slip, we need to properly determine when the wall starts sliding and the system enters the slip regime. To make sure that we precisely identify the times at which the wall starts moving, while ignoring small oscillations of the wall velocity after a slip event (see Fig. 3 (b-c)), we use the following protocol that consists of two parts.

These two parts could be labeled as ‘rough’ and ‘fine’. The ‘rough’ part is based on the fact that the top wall velocity, v_x , tends to differ by several orders of magnitude in the slip and stick phases. We choose a threshold $v_f^* = 2 \times 10^{-3}$ which is an order of magnitude smaller than a typical velocity during a slip event and at least an order of magnitude larger than the average velocity during the stick phase. The rough part of the algorithm identifies the times at which v_x crosses the value v_f^* as the beginnings of individual slip events. To avoid considering small oscillations following a slip event as separate events, we require that all slip events are separated by more than $150\delta t$. In the second part, we fine-tune the starting times of the slip events as follows. First, we compute the mean, \bar{v}_x , and standard deviation, s_{v_x} , of v_x for all times at which $v_x < v_f^*$. These values are used to define a new threshold $v_f = \bar{v}_x + s_{v_x} \approx 2.5 \times 10^{-4}$. Finally, we adjust the times identified as the beginning of slip events, in the ‘rough’ part of the algorithm, by decreasing them until the value of v_x drops below v_f . We have verified that the precise values of the thresholds have only a minor influence on the results that follow.

For this paper, the identification of the end of a slip is not necessary. However, we provide a protocol that is designed to avoid premature detection of a slip end due to small oscillations following a slip. To achieve this we require that the wall velocity v_x at the end of the slip event, as well as its average over the preceding 50 states, is smaller than v_f^* . The chosen number of states roughly corresponds to the period of small oscillations following a slip event.

B. Force networks and differential force networks

The available information about particle interactions can be encoded by a force network. In this paper, we utilize a force network defined by normal interparticle forces, however, force networks defined by tangential (or total) forces could be considered as well.

We start by defining a time dependent contact network, $\text{CN}(t)$, that describes which particles are in contact at a given time t . This network is based on vertices $V_c(t) = \{v_i\}_{i=1}^N$ that correspond to the centers of system particles, $\{p_i\}_{i=1}^N$ (we do not consider wall particles). An edge $\langle v_i, v_j \rangle$ belongs to $\text{CN}(t)$ if the particles p_i and p_j are in contact at time t .

The force network, $\text{FN}(t)$, is defined by assigning weights to the edges of $\text{CN}(t)$, so that the weight of the edge $\langle v_i, v_j \rangle$ is the magnitude of the normal force acting between the particles p_i and p_j . Figures 4(a, b) show the force network at two different times before a slip event, depicted in Fig. 3, occurs. The time evolution of the force network is illustrated by the animations in Supplementary Materials.

One possibility for encoding differences between the force networks $\text{FN}(t)$ and $\text{FN}(t + \delta t)$ is to consider a differential force network, $\text{DFN}(t)$, that expresses how much

the force network changes between two considered time instances. Because the force bearing contacts might be created or destroyed during the time interval $[t, t + \delta t]$, the edges of $\text{DFN}(t)$ are given by the union of the edges in $\text{CN}(t)$ and $\text{CN}(t + \delta t)$. The weights of the edges in $\text{DFN}(t)$, defined as the absolute value of the difference of its weights in $\text{FN}(t)$ and $\text{FN}(t + \delta t)$, indicate the changes in forces acting between the particles between time t and $t + \delta t$. If an edge is not present in $\text{FN}(t)$ or $\text{FN}(t + \delta t)$, then its weight in the corresponding force network is set to zero. Figures 4(c) and (d) show two differential force networks. Note that the weights of the edges in $\text{DFN}(t)$ grow strongly as the system approaches a slip event, see also Supplementary materials for animations.

To study $\text{DFN}(t)$ we compute the maximum force value, f^* , such that the edges of $\text{DFN}(t)$ with weights larger than f^* percolate through the system. In what follows, we will consider both left-right and top-bottom percolation, and call the corresponding f^* values f_{plr} and f_{ptb} , respectively.

C. Measures derived using persistent homology

To identify complex structures exhibited by force networks we use persistent homology (PH) which is one of the major tools of topological data analysis. PH has been extensively used to describe complex patterns in a variety of settings [42–45]. There is also a growing body of literature that uses PH to study granular systems exposed to compression [30, 33], vibrations [31, 35, 46], or shear [47]. In this section, we only provide a brief summary of PH and introduce the measures used in this paper. Detailed guidance for using PH to analyze force networks is available elsewhere [34].

Every weighted network in two spatial dimensions can be represented by two persistence diagrams, PDs, that provide a compact but informative description of the structure of this network. Each diagram is a collection of points in a plane and these points describe how the topology of sub-graphs containing only the edges with weights exceeding some threshold T changes as the value of T is decreased. The first persistence diagram, PD_0 , encodes the structure of connected components that can be related to so-called ‘force chains’. To be more precise, every point $(b, d) \in \text{PD}_0$ corresponds to a connected component that appears at the threshold $T = b$ and merges with another connected component for $T = d$. Hence, the lifespan of the point (b, d) , given by $b - d$, indicates the prominence of the connected component corresponding to this point. Similarly, a point $(b, d) \in \text{PD}_1$ indicates that a loop appears in the sub-graph for $T = b$. Once a loop appears at $T = b$ it is present in all the sub-graph for all $T < b$. In this paper we follow the convention introduced in [34] and set $d = 0$ for every point in PD_1 . Supplementary materials include an animation of the force network and the corresponding PDs for a selected slip event.

Information contained in PDs can be further compressed in several ways. One possibility of compressing a PD to a single number is to compute the sum of the lifespans of all the points in the diagram. We call this quantity total persistence, TP0 or TP1 depending on whether it is extracted from PD₀ or PD₁. In previous studies TP was found to be a very useful quantity e.g., in [47] TP1 was correlated with the viscosity of a shared suspension, showing directly the connection between force network properties and rheological properties of the considered system.

In addition to considering system-wide averages at individual times (such as TP), we also use PH to quantify the *time evolution* of the force network. The space of persistence diagrams is a complete metric space for a variety of metrics [41]. The main idea behind defining a metric on this space is to match the points in one diagram with the points in the other. This matching can be done in different ways leading to different metrics. In this paper we consider the matching that minimizes the sum (W2 distance) of the squares of L_∞ distances between the matched points. If the W2 distance is computed between the PD₀ (PD₁) diagrams corresponding to the force networks FN(t) and FN($t + \delta t$), we denote it by W2B0 (W2B1). For simplicity we suppress the time argument on W2's. The distance depends on the difference between the times at which the compared PD's are computed. We have verified that during the stick phases this dependence is approximately linear for the considered value of δt , suggesting that the frequency of the time outputs is sufficient to resolve the temporal evolution of the force network [48].

D. Broken, mobile and nonmobile contacts

In this section, we define the measures that we use to study the changes of the contact network CN(t) and the nature of the contacts. If the contact between the particles p_i and p_j is present at time t , but not at $t + \delta t$, we say that the contact is broken. A simple measure to quantify the difference between CN(t) and CN($t + \delta t$) is given by the ratio, $r_{bc}(t)$, between the number of broken contacts and the total number of contacts at time t . If the contact between two particles disappears, then the force previously acting between them vanishes and we refer to this force as a broken force. The average broken force, f_{bc} , is defined as the sum of all broken forces divided by the number of broken contacts.

Until now, we only discussed quantities based on the normal component of the force acting between the particles. In Sec. IV we also discuss two quantities that involve both the magnitude, F_t , of the tangential component of the force and the magnitude, F_n , of the normal component. One considered quantity is simply the ratio, F_t/F_n , calculated separately for each contact and then averaged over all contacts. The other related quantity is the ratio of mobile to non-mobile contacts, RMN. A con-

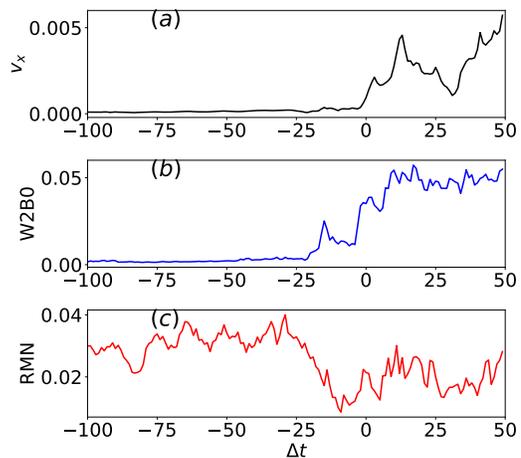

FIG. 5. (a) Top wall velocity in the x direction, v_x , of the slip event shown in Fig 3 and Fig. 4. The value $\Delta t = 0$ indicates the time at which the event starts. (b) W2B0, (c) ratio of mobile to non-mobile contacts, RMN.

tact between two particles is mobile if the ratio F_t/F_n is at the Coulomb threshold, μ . Note that within the implemented model $F_t \leq \mu F_n$, so that mobile contacts are the ones for which F_t/F_n reaches the largest possible value. In our computations, a contact is considered mobile if $F_t/F_n > \mu - \epsilon$, with $\epsilon = 10^{-3}$. All other contacts are called non-mobile. As a reminder, we do not consider particle-wall contacts.

IV. RESULTS

A. Motivation: A single slip event

To motivate the following discussion, we first discuss a single slip event that starts at time t_0 . We are interested in the behavior before the start of this event. Thus, we present the results in terms of $\Delta t = t - t_0$.

Figure 5(a-c) shows the velocity of the top wall, v_x , W2B0, and the ratio of the mobile and non-mobile contacts, RMN. Note that due to our definition of t_0 the wall is essentially at rest for $\Delta t < 0$. However, Fig. 5(b) shows that W2B0, which measures changes in the structure of the force network, increases significantly already around $\Delta t = -20$. This indicates that the force network starts changing rapidly as the system approaches a slip event. The fact that the W2B0 detects this increased activity suggests its potential for predicting slip events. On the contrary, RMN does not exhibit any clear trend. This finding motivates a more careful statistical analysis of a large number of slip events. Such analysis, presented in what follows, demonstrates that the difference between W2B0 and RMN, shown in Fig. 5, is not just a coincidence.

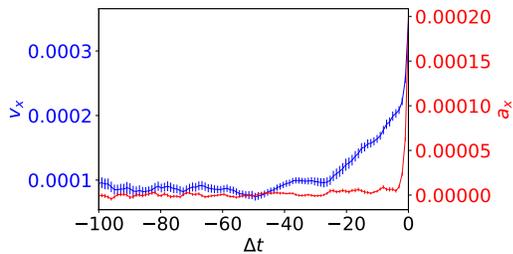

FIG. 6. The mean of the wall speed, v_x , and acceleration, a_x before slip events, averaged over all slip events. The value $\Delta t = 0$ corresponds to the beginning of the slip events, t_0 . In this and the following figures, the error bars show the standard errors.

B. Statistical Analysis

To study the behavior of the system over a large number of slip events, we average the considered measures over different slips as follows. For each event we record the individual measures for the last 100 consecutive samples before its beginning, that is for $\Delta t \in \{-100, -99, \dots, 0\}$. Then, we compute average of each measure for fixed values of Δt .

Figure 6 shows the mean of wall velocity, v_x , and of its acceleration, averaged over the complete set of 465 slip events. Due to our definition, the wall almost does not move before the slip starts at $\Delta t = 0$. In particular, the velocity of the wall in the x -direction is smaller than 2.5^{-4} [49]. However, there is a change in the trend around $\Delta t = -25$. For $\Delta t < -25$ the mean v_x fluctuates while it increases steadily for $\Delta t > -25$ but this increase is orders of magnitude smaller than the increase observed at the beginning of the slip. Note that the mean roughly doubles in the time interval $[-25, -1]$, and then it almost doubles again during a single time step as the slip starts.

We proceed by discussing two sets of different measures. The first set consists of the measures that are obtained as (global) system-wide averages of the considered properties of the system at a given time. The second set of measures is devised to assess micro and mesoscale changes that occur as the system evolves in time. We will show that these two sets of measures provide very different information about the system's behavior before a slip event.

1. Global measures

Figure 7 shows our results for the set of measures based on the system-wide averages. Averaging the considered measures over a large number of events produces reasonably smooth results, despite the large variability of these quantities between individual slip events. For brevity, we do not discuss this variability in more quantitative terms here. In the rest of this paper, we only report the standard errors to indicate how well the individual means are

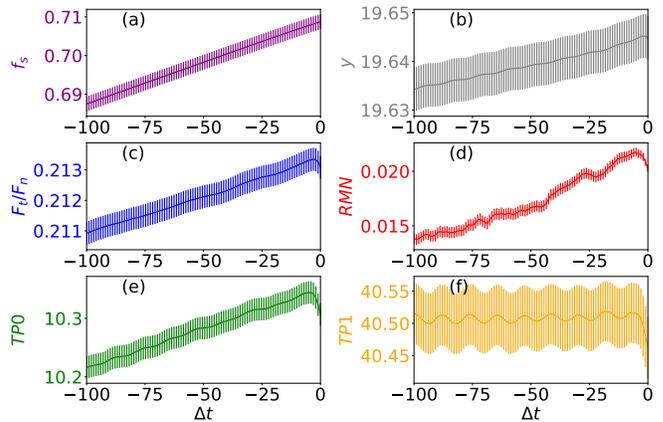

FIG. 7. Global measures averaged over all slip events: (a) spring force, f_s , (b) y position of the top wall, (c) the ratio F_t/F_n , (d) the ratio of mobile to non-mobile contacts, RMN, (e) TP0, (f) TP1.

estimated.

Figure 7(a) depicts the force pulling the top wall. This measure is not strictly speaking a system-wide average but we show it since the results are similar to other quantities presented in this figure. The value that this force reaches, before individual slips, varies considerably (see, e.g. [18, 50] for examples of simulations in similar settings). This variability shows the stochastic nature of stick-slip type dynamics. Nevertheless, Fig. 7(a) indicates that, despite large variations, the mean of the force pulling the top wall is well estimated and increases linearly.

Figure 7(b) shows that the mean of the y coordinate of the wall position increases also approximately linearly with time, since the system expands as the force applied by the spring increases. This effect is known as Reynolds dilatancy and is caused by increased applied stress. Note that the effect is very weak and the system only expands by a small fraction of the particle diameter.

Figures 7(c, d) show two related quantities defined in Sec. III. The ratio of tangential and normal forces, F_t/F_n , and the ratio of mobile to nonmobile contacts (RMN). The value of F_t/F_n increases linearly with the applied spring force. This is not surprising because, in a static system, one expects F_t to counteract the applied force and thus the linear dependence seems natural. While this argument is more appropriate in a limit of a single layer of separate particles between the walls, Fig. 7(c) shows that it holds, at least on average, for the system considered here as well. The increase of RMN is a consequence of the increase of tangential forces, ignoring for the moment the fact that the normal force may change as well. It is worth pointing out that these simple scaling results hold only on average and the behavior of the individual quantities can be very different for a single event, see Fig. 5. We also note that the total normal force between the particles increases as slips are approached, making

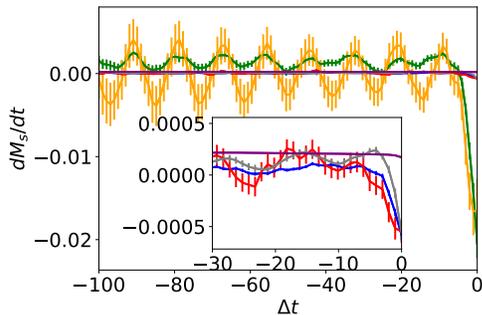

FIG. 8. Derivatives of the global measures, shown in Fig. 7, are depicted using the same colors. The inset zooms into the measures whose change is hardly visible in the main plot.

the above argument only approximate.

The next two global, system-wide measures are derived from persistence diagrams. Figure 7(e) shows the total persistence for connected components, TP0, which increases linearly. This is not surprising since this measure is expected to scale with the applied force. The behavior of TP1, shown in Fig. 7(f) is different and deserves further attention. Recall that TP1 is the sum of the lifespans of the points in the PD_1 . The birth coordinate of a point in PD_1 is given by the magnitude of the weakest force in the loop corresponding to this point. Because the death coordinate is always zero, the lifespan of the point is equal to its birth coordinate. The oscillations of the forces on the weakest links cause oscillations of TP1. It turns out that oscillations of the forces on the weakest links are caused by minor oscillations of the top wall, barely visible in Figure 7(b). These oscillations, in turn, are essentially damped aftershocks following slip events. Additional simulations (not shown here for brevity) of the systems for which the average distance between the top and bottom wall is approximately twice as large (carried out by doubling the number of particles) show that the period of these oscillations scales with the system height. This finding suggests that the oscillations are caused by compression waves propagating through the system in the y direction.

To further show that the system-wide averages do not exhibit any clear signs of the approaching slip, as well as to facilitate comparison with the results presented in Sec. IV B 2, we consider their derivatives. Figure 8, which depicts the derivatives of the measures presented in Fig. 7, indicates that the derivatives do not change dramatically, except for a couple of data points right before a slip occurs. This behavior, very close to the beginning of a slip event is due to relaxation of the forces caused by the fact that the system starts slowly evolving and breaking up contacts between the particles. However, this relaxation only happens very close to the slip itself and is not particularly useful as a slip precursor. Hence, we conclude that global measures do not capture the behavior which could be useful for predicting an imminent slip event. This motivates the need for measures that

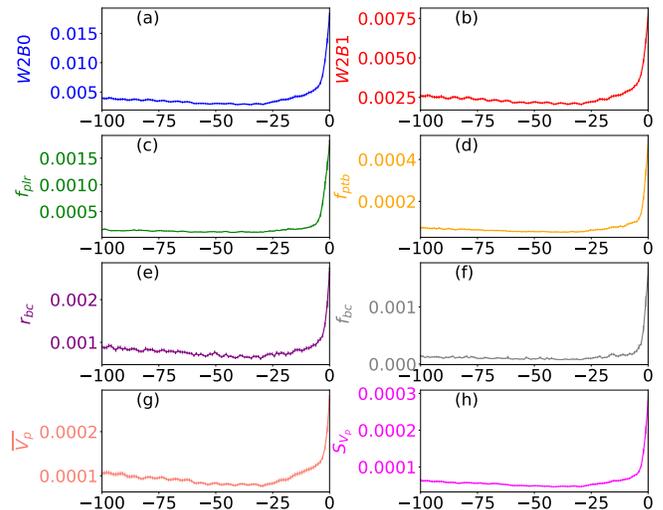

FIG. 9. (a) W2B0 distance, (b) W2B1 distance, (c) the horizontal percolating differential normal force, f_{plr} , (d) the vertical percolating differential normal force, f_{ptb} , (e) the ratio of broken contacts to total contacts, r_{bc} , (f) the average normal force of broken contacts, f_{bc} , (g) the mean of system particle speed, \bar{v}_p , (h) the standard deviation of system particle speed, s_{v_p} .

assess the evolution of the system on the micro (particle) and mesoscopic spatial scales.

2. Local measures

In Sec. III we defined measures that are capable of quantifying the changes of the system on the particle scale as well as on mesoscopic scales relevant to our study of the evolution of the force network. We remind the reader that to quantify these changes we first compare local and mesoscopic differences between the consecutive samples and only then aggregate them to a single number quantifying the difference. As discussed previously in the context of W2 distances, the output rate in our simulations is sufficiently high so that the main features of the results are rate-independent.

Figure 9 shows the results, again averaged over all slip events. Figures 9(a, b) depict the W2B0 and W2B1 distances measuring the differences between two consecutive persistence diagrams PD_0 (PD_1) that capture the structure of the connected components (loops) present in the force network. The measures, shown in Fig. 9(c, d), also evaluate temporal changes in the force network structure by utilizing the notion of the differential force network. The parts (e, f) focus on broken contacts: part (e) shows the ratio of the number of broken contacts divided by the number of all contacts, and (f) shows the average normal force of these broken contacts. Finally, the parts (g, h) show the mean speed, \bar{v}_p , of the system particles, and its standard deviation, s_{v_p} . These quantities are calcu-

lated as $\bar{v}_p = \sum_{i=1}^N v_i/N$ and $s_{v_p} = \sqrt{\sum_{i=1}^N (v_i - \bar{v}_p)^2/N}$, where v_i is the speed of the i -th particle.

Although there is no direct connection between the measures presented in Fig. 9, they all show similar behavior. In particular, all of them start growing rapidly before the beginning of a slip event. We recall that this behavior is similar to the behavior of the wall velocity, v_x , see Fig. 6. Therefore, the trend exhibited by the dynamic local measures is completely different from the one exhibited by the static global measures, Fig. 7, or their derivatives, Fig. 8.

All measures shown in Fig. 9 quantify the time evolution of the system on either particle scale or mesoscale. The fact that these measures increase before the onset of a slip event indicates that the evolution on both particle scale and mesoscale intensifies before the slip. However, this increased activity is not detected by the global measures. This suggests that the increased activity is limited to local fluctuations. We expect that these fluctuations intensify until they eventually reach a critical level and trigger the slip event, which leads to global rearrangements. Notice that these fluctuations do not only affect the force networks but also the movement of the particles, as indicated by the increase of their velocities shown in Fig. 9(g - h).

Before closing this section, we comment on the very different behavior of the wall velocities in the x and y directions (compare Figs. 6 and 8). This difference is caused by the different nature of these two measures. The velocity v_y depends on the (global) pressure while the velocity v_x depends on local interactions between the wall and the particles.

V. CONCLUSIONS

We consider a granular system exhibiting intermittent dynamics known as the stick-slip regime. To detect the slip events, we use a strict a posteriori method, based on the wall movement. Even though the system is essentially static before slip starts, we can identify system measures that dramatically change their behavior as the system approaches a slip event.

The measures that we consider in this paper fall into two categories. The first category of global measures is obtained by averaging over the whole system. We find that before a slip event these measures show (on average) approximately linear behavior. There is no clear change in their behavior almost until the slip starts. The second category of the measures quantifies local and mesoscopic changes of the system. Thus, computing them requires knowledge of the system at different time instances. We find that the measures in this category behave differently. Namely, they start to increase in a nonlinear fashion well before a slip starts. The local nature of these measures suggests that their behavior is caused by spatial and temporal fluctuations in the system which cannot be detected by the global measures.

We hypothesize that the intensity of the fluctuations in the system increases until it overcomes the stabilizing effects of the force networks and triggers a slip event. Therefore, information about the evolution of the system on micro and mesoscopic scales seems to be vital for accurately predicting the occurrence of a slip.

We expect that the local measures, introduced in this paper, could be used to predict an upcoming slip event. However, the variations between different slip events suggest that more advanced statistical methods involving either machine learning or some complementary approach will be needed to achieve this goal. The development of such methods will be the subject of our future work.
